SI.I Simulation Set-Up

This section is provided to improve the reproducibility of the results presented in this study.

SI.I.1 State Points

Tables SI.I, SI.II, SI.III, SI.IV, SI.V, SI.VI, SI.VII, and SI.VIII contain the state points that were simulated for ethane, propane, *n*-butane, *n*-octane, isobutane, isohexane, isooctane, and neopentane, respectively. The first 10 state points of each table correspond to five isochores while the last 9 points are for the supercritical isotherm. The number of state points, the specified reduced temperatures, and the spacing between neighboring densities were recommended by the developers of the ITIC approach (J. Richard Elliott and Seyed Mostafa Razavi). It has been demonstrated that these points are sufficient for accurate calculation of $\rho_{\mathrm{l}}^{\mathrm{sat}}$, $\rho_{\mathrm{v}}^{\mathrm{sat}}$, and $P_{\mathrm{v}}^{\mathrm{sat}}$.[1,2] Note that the temperatures (T_{sim}), box lengths (L_{box}), and number of molecules (N_{M}) are the exact values used in simulation while the density (ρ) is approximate (rounded) since it is calculated from L_{box}, N_{M}, and the molecular weight.

SI.I.2 GROMACS Input Files

We have provided example input files for simulating isooctane at 653.0 K with the TraPPE-UA force field in GROMACS (see attached .gro, .top, and .mdp files).

Table SI.I: State points simulated for ethane.

SI.II Potoff Generalized

Figure SI.1 provides the simulation results for the Potoff generalized force field for branched alkanes. Compare to Figure 4 in the main text.

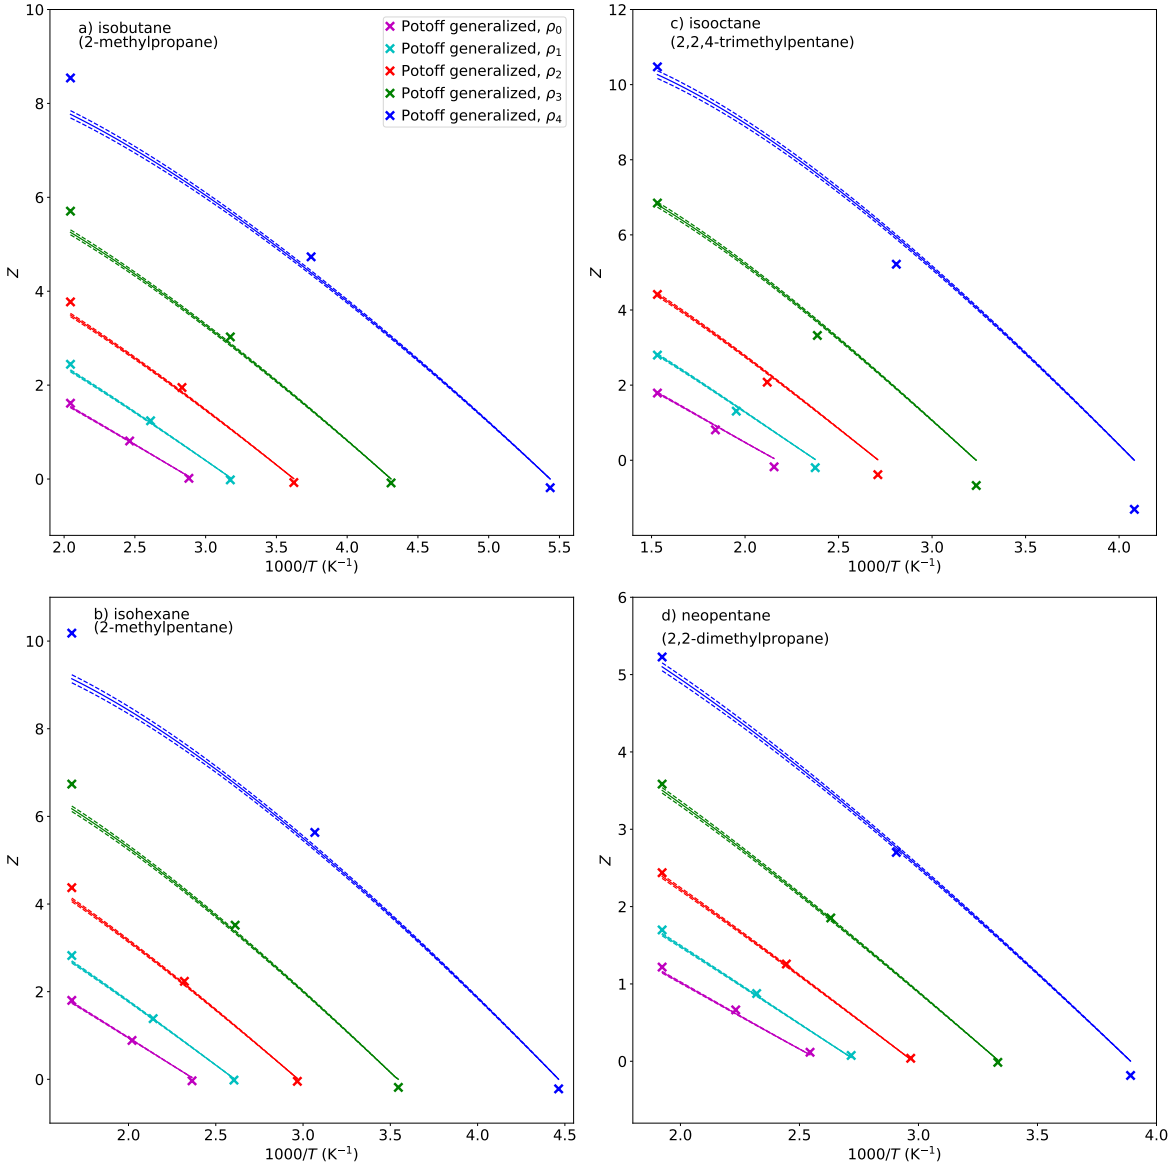

Figure SI.1: Compressibility factors (Z) along isochores for branched alkanes deviate strongly at higher pressures using the Potoff generalized force field. Panels a)-d) correspond to isobutane, isohexane, isooctane, and neopentane, respectively. Symbols, lines, uncertainties, and formatting are the same as those in Figure 3.

SI.III MCMC Example

In this section we present typical results from an MCMC run. All of the MCMC runs performed in this study used 10000 MCMC steps for the burn-in period and an additional 10000 MCMC steps for the production period. The proposal distribution variances (s_ϵ^2 and s_σ^2) were tuned every 100 MCMC steps during the burn-in period. Specifically, if the acceptance ratio was less than 20%, the variances were decreased by a factor 0.9^2. If the acceptance ratio was greater than 50%, the variances were increased by a factor of 1.1^2. During the production period, every 20 MCMC steps are stored to account for auto-correlation. Thus, the posterior predictive results for $\rho_{\mathrm{l,MCMC}}^{\mathrm{sat}}$, $P_{\mathrm{v,MCMC}}^{\mathrm{sat}}$, and Z_{MCMC} are based on 500 ϵ_{MCMC}–σ_{MCMC} parameter sets.

Figures SI.2-SI.3 provide an example of the MCMC results for ethane with $\lambda_{\mathrm{CH_3}} = 16$. Figure SI.2 Panels a)-c) demonstrate that a burn-in period of 10000 steps is sufficient for an ergodic-like sampling of σ, ϵ and $\log(Pr)$, respectively. Panels d)-e) show that the respective distributions for σ and ϵ appear to be normal. Note that the histograms of Panels d)-f) only include production period samples. The acceptance rate for proposed moves in ϵ and σ was 28.8%.

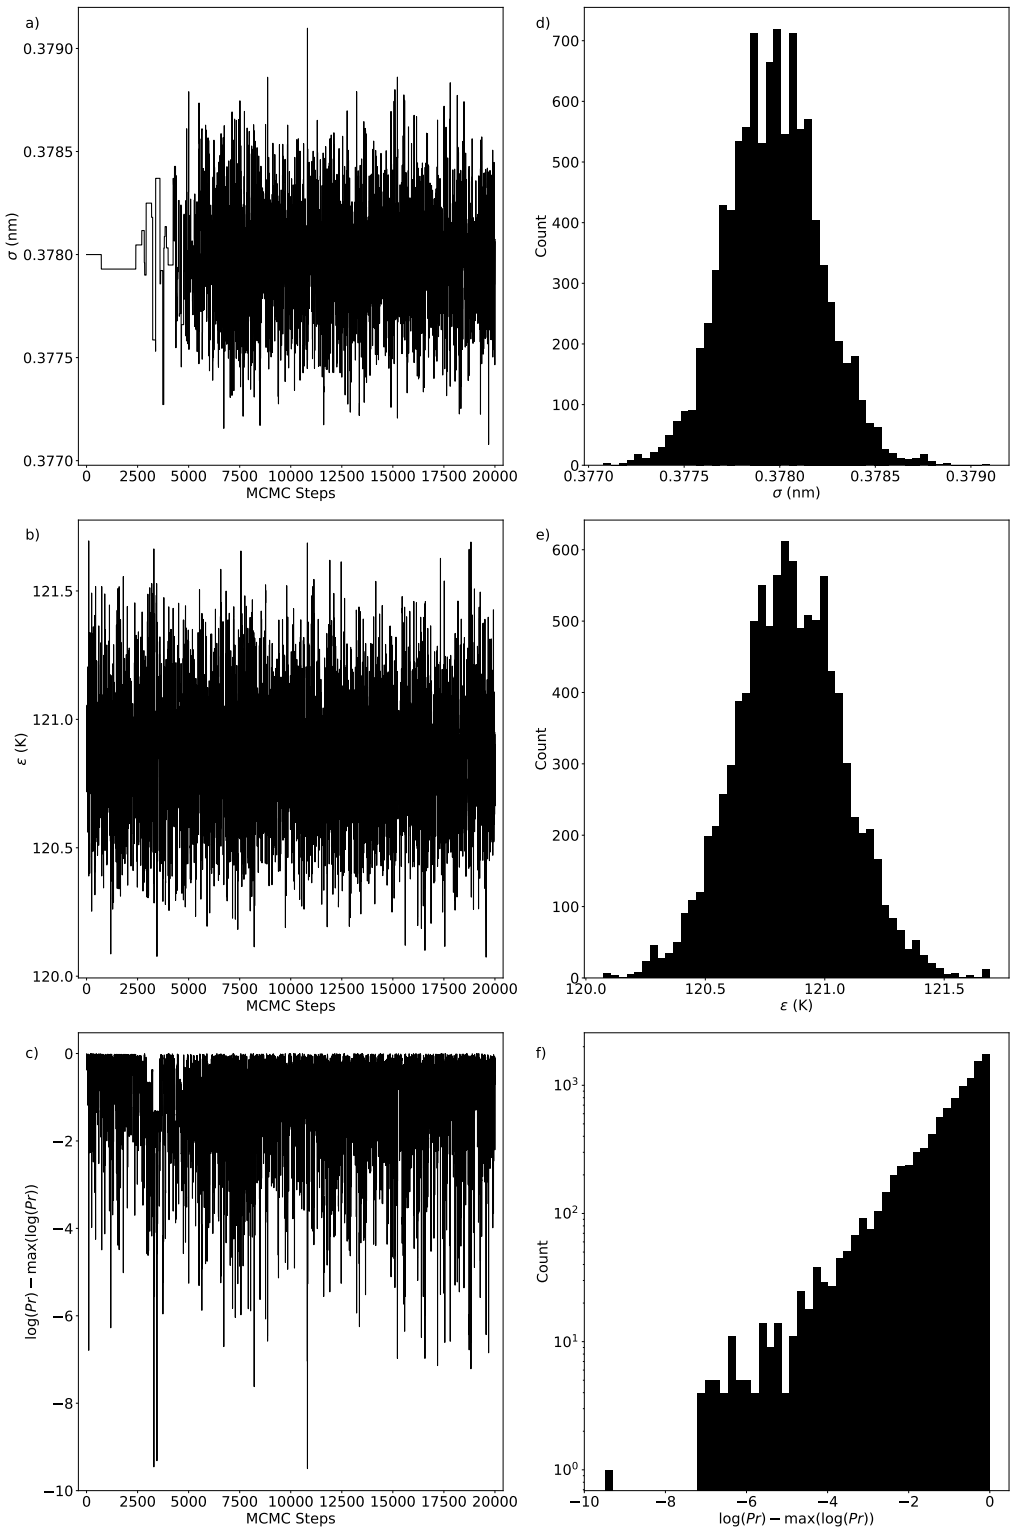

Figure SI.2: Panels a)-c) plot the respective traces of σ, ϵ and $\log(Pr)$, where Pr is the posterior. Panels d)-f) plot histograms of the production period samples for σ, ϵ and $\log(Pr)$, respectively. Note that $\log(Pr)$ is normalized by the maximum $\log(Pr)$.

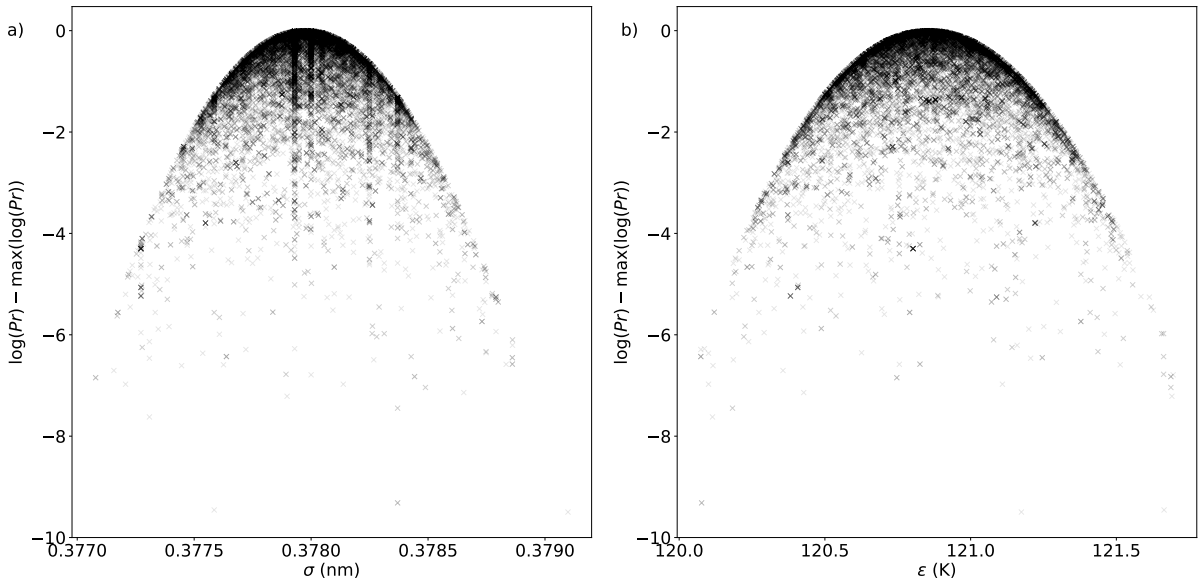

Figure SI.3: Panels a)-b) plot the dependence of $\log(Pr)$ (normalized by the maximum $\log(Pr)$, where Pr is the posterior) with respect to σ and ϵ.

SI.IV Error Model

Figure SI.4 presents the percent deviation between the surrogate model (SM) and literature (lit) VLE values using the TraPPE-UA and Potoff force fields for ethane, propane, *n*-butane, and *n*-octane. From this figure, an approximate surrogate model uncertainty was deduced such that most of the points, with their corresponding error bars, would lie within this uncertainty region. Note that the majority of literature values are for $T_r > 0.6$, therefore, we used our best judgment when extrapolating the surrogate model uncertainties to $T_r = 0.45$.

There are two likely reasons to explain why the percent deviations in $\rho_{\mathrm{l}}^{\mathrm{sat}}$ increase with respect to temperature. First, ITIC neglects the higher order virial terms that become more important at higher temperatures. Second, we use the REFPROP B_2 and B_3 values, rather than those of the force field. By contrast, the larger percent deviations in $P_{\mathrm{v}}^{\mathrm{sat}}$ with decreasing temperature are attributed primarily to the difference in orders of magnitude

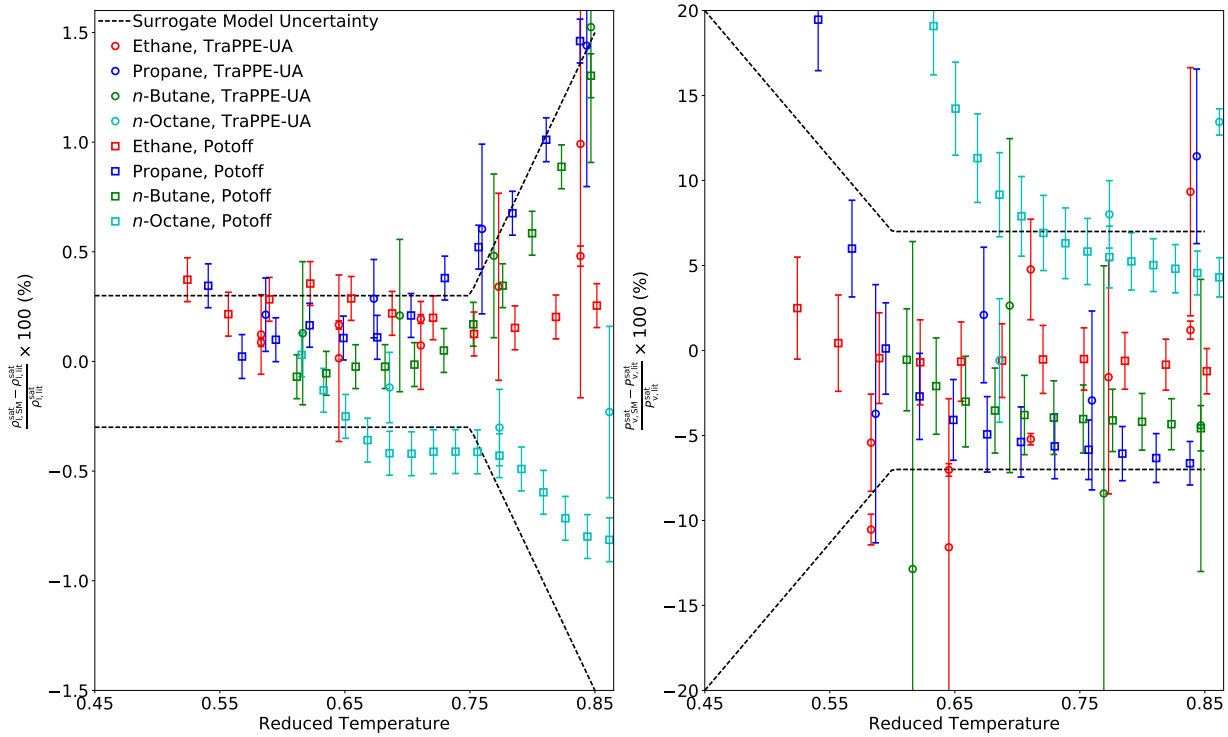

Figure SI.4: Panels a)-b) demonstrate how well the surrogate model uncertainty agrees with the percent deviations between the surrogate model and literature values for $\rho_{\mathrm{l}}^{\mathrm{sat}}$ and $P_{\mathrm{v}}^{\mathrm{sat}}$, respectively. Reduced temperature is relative to the REFPROP T_c. The TraPPE-UA and Potoff literature values were obtained using GEMC[3,4] and GCMC,[5] respectively. Error bars represent statistical uncertainties that were obtained using replicate simulations. The error bars for TraPPE-UA were obtained from References 3,4, or alternatively on the TraPPE website. No attempt was made to determine if these are standard deviations or 95% confidence intervals. The error bars for the Potoff model are a constant 0.1% for $\rho_{\mathrm{l}}^{\mathrm{sat}}$ and 0.5-3% for $P_{\mathrm{v}}^{\mathrm{sat}}$, increasing linearly with decreasing reduced temperature. The values 0.5-3% were reported in Reference 5. As Reference 5 did not report uncertainties for $\rho_{\mathrm{l}}^{\mathrm{sat}}$, the value of 0.1% is based on some of Potoff's more recent work.[6]

for $P_{\mathrm{v}}^{\mathrm{sat}}$, since the virial coefficients should not impact $P_{\mathrm{v}}^{\mathrm{sat}}$ at lower temperatures.

Aside from these expected trends, some other unexplained deviation trends are observed for a specific property, compound, and/or force field. However, it is not readily obvious if these deviations are caused by limitations in the surrogate model or the literature values themselves. For example, the TraPPE-UA and Potoff literature values were obtained using GEMC[3,4] and GCMC,[5] respectively. These Monte Carlo methods can suffer from low insertion acceptance at $T_r < 0.7$, which can result in erroneous VLE values, for $P_{\mathrm{v}}^{\mathrm{sat}}$ in particular. It is not our intention to imply that our values are better than either the TraPPE-UA or Potoff literature values, but rather we wish to emphasize that it should be expected that our approach would not yield exactly the same values as other methods. It is for this precise reason that our surrogate model uncertainty is larger than the statistical uncertainties which are typically reported in the literature.

SI.V Additional Properties

Figure SI.5 compares the MCMC results of different λ values for Z along the supercritical isotherms of the *n*-alkanes studied. The purpose of this plot is to demonstrate deviations in the slope of Z with respect to density for a constant temperature, i.e. $\left(\frac{\partial Z}{\partial \rho}\right)_T$, which is related to A_{01}^{dep} and A_{02}^{dep} (see Equation 29). The deviations at high densities along the supercritical isotherm are already explained in the main text. For this reason, the insets focus on the low density region. Inset in Panel a) shows that the 13-6 potential under-predicts Z at low density while it agrees well at high density. Recall that for ethane the 13-6 potential is very accurate at predicting Z and even the slope of Z along the isochores, i.e. $\left(\frac{-\partial Z}{\partial (1/T)}\right)_\rho$. However, the 13-6 potential does not appear to have the correct slope for Z along the isotherm, i.e. $Z\left(\frac{\partial Z}{\partial \rho}\right)_T$. The same trend is observed for the 14-6 potential in all four *n*-alkanes, namely, the improvement for predicting Z at high densities typicaly results in under-prediction of Z at low densities.

Figure SI.6 compare the MCMC results of different λ values for U^{dep} along the isochores of the *n*-alkanes studied. The purpose of this plot is to demonstrate deviations in U^{dep} and the slope of U^{dep} with respect to temperature for a constant density, i.e. $\left(\frac{\partial U^{\text{dep}}}{\partial T}\right)_\rho$, which are related to A_{10}^{dep} and A_{20}^{dep}, respectively (see Equations 27-28). Definitive conclusions are difficult due to the relatively large uncertainty in the REFPROP correlations, approximated to be 5%. However, Panel a) demonstrates that at T^{sat}, i.e. the lowest temperature for a given isochore, $\lambda = 15$ accurately predicts U^{dep} while $\lambda > 15$ and $\lambda < 15$ consistently under- and over-predict U^{dep} at T^{sat}. By contrast, $\lambda = 13$ agrees more closely with U^{dep} at T^{IT}, i.e. the highest temperature, while $\lambda > 13$ under-predict U^{dep} at T^{IT}. A similar trend is observed for propane, *n*-butane, and *n*-octane, namely, $\lambda = 16$ and $\lambda = 14$ are more accurate at T^{sat} and T^{IT}, respectively. These results suggest that all values of λ are inaccurate for $\left(\frac{\partial U^{\text{dep}}}{\partial T}\right)_\rho$ and are only reliable for U^{dep} at certain conditions.

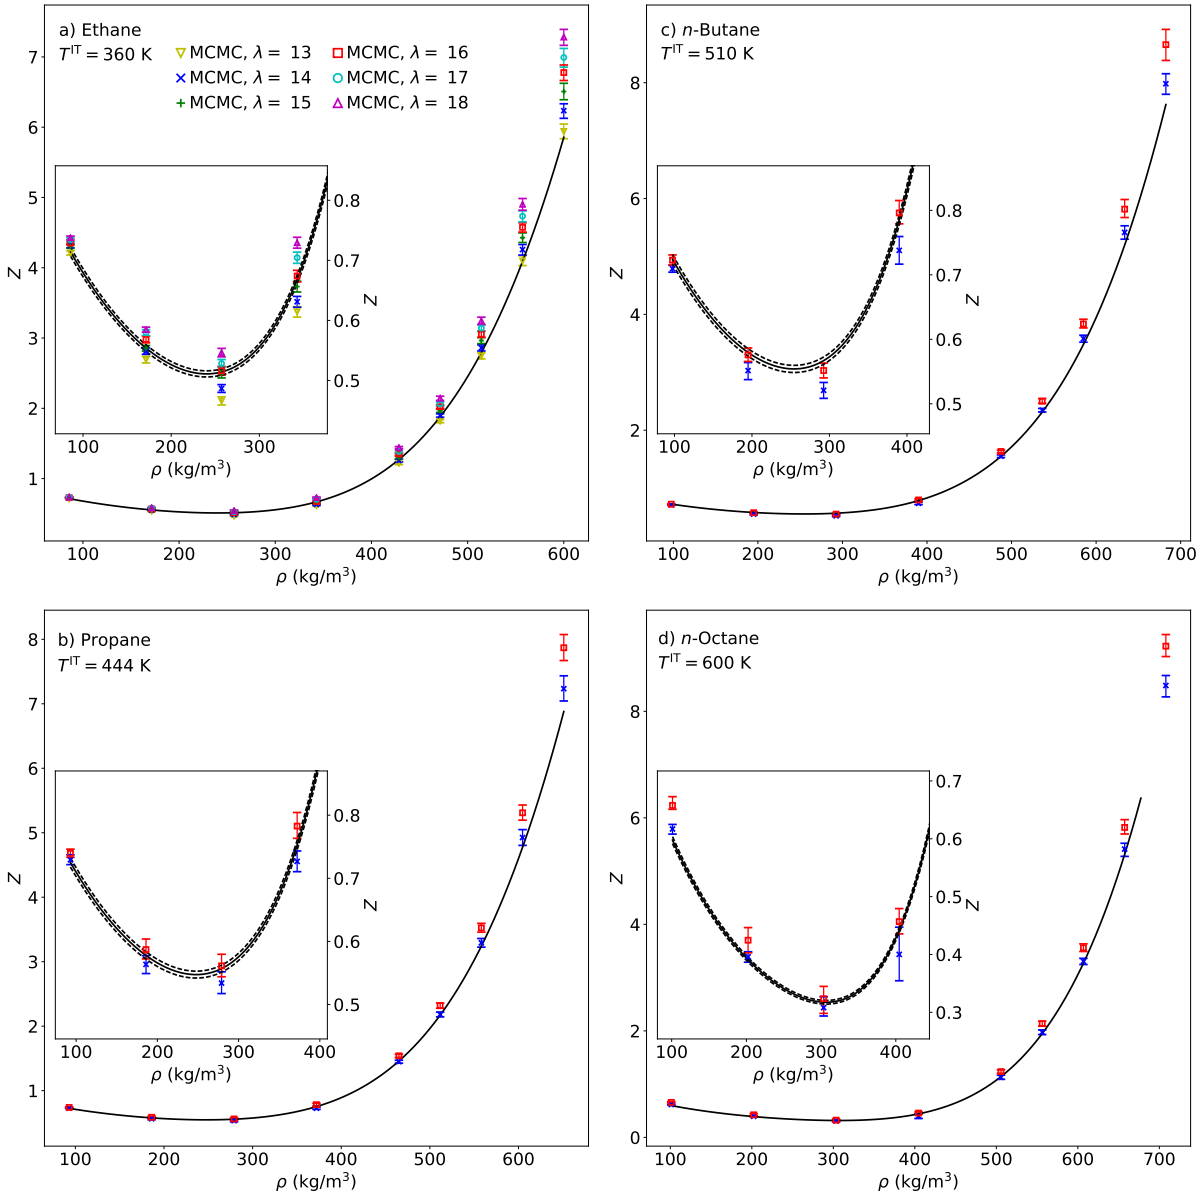

Figure SI.5: Z_{MCMC} along the supercritical isotherms for different λ values. Panels a)-d) correspond to ethane, propane, *n*-butane, and *n*-octane, respectively. Solid lines are the REFPROP correlation with dashed lines (included only in the insets) representing a 1% uncertainty.

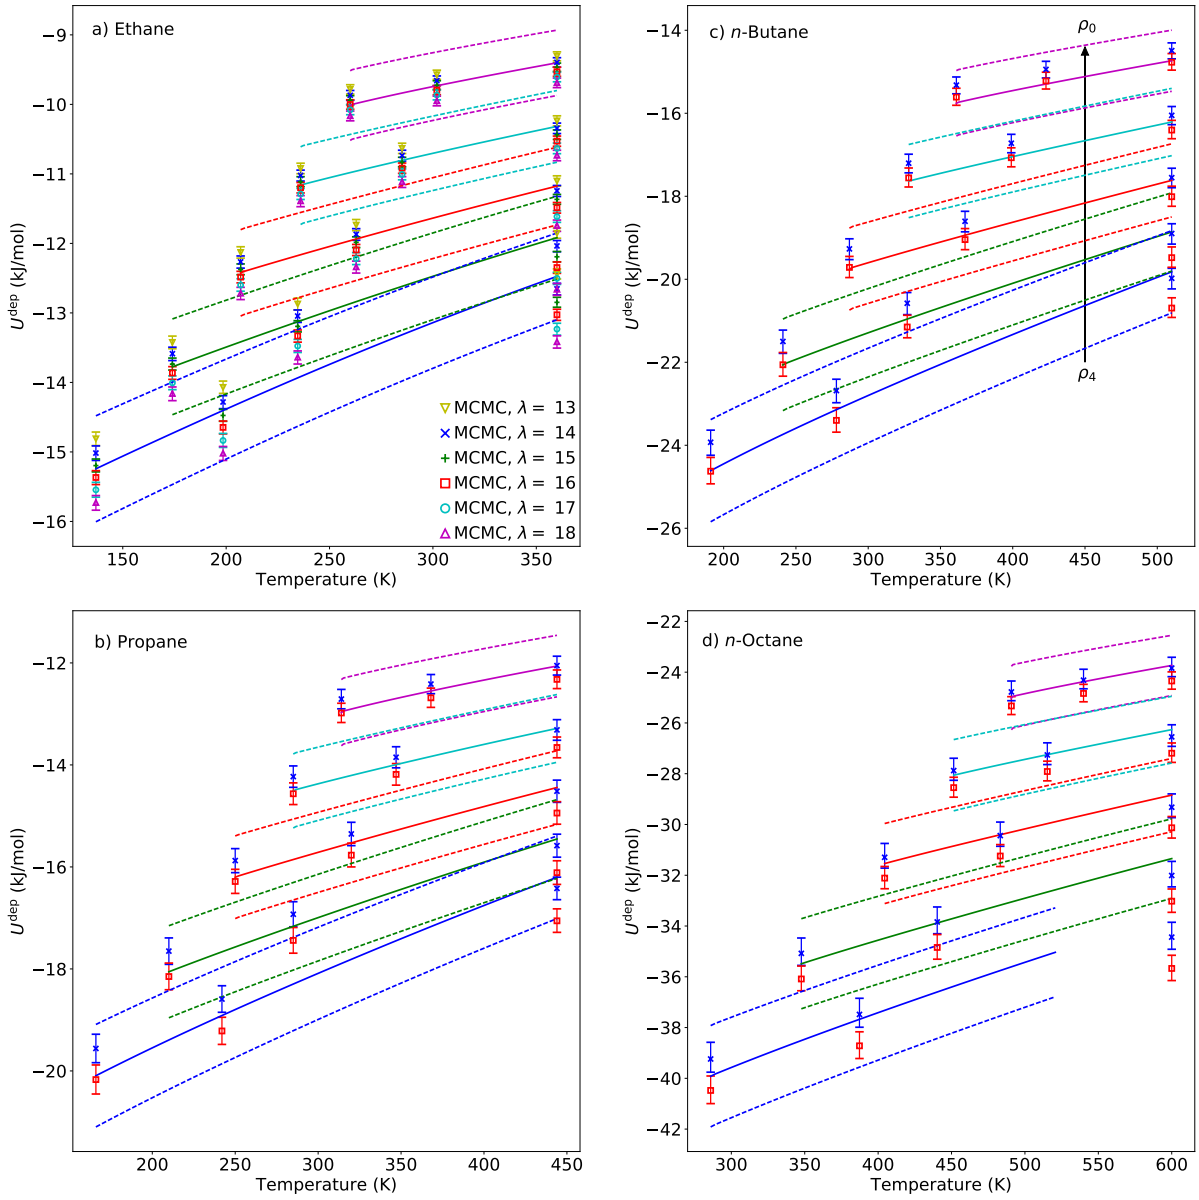

Figure SI.6: $U^{\text{dep}}_{\text{MCMC}}$ along the isochores for different λ values. Panels a)-d) correspond to ethane, propane, *n*-butane, and *n*-octane, respectively. Solid lines are the REFPROP correlation with dashed lines representing a 5% uncertainty. Line colors of different isochores correspond with Figures 3-4 in main text.
